Onset and Exacerbation of Obsessive-Compulsive Disorder in Pregnancy and the Postpartum Period

Ariadna Forray, MD; Mariel Focseneanu, MD; Brian Pittman, MS; Christopher J. McDougle, MD; and C. Neill Epperson, MD

Background: The primary goal of this study was to examine the impact of pregnancy, childbirth, and menstruation on the onset of obsessive-compulsive disorder (OCD) and/or exacerbation of OCD symptoms.

Method: One hundred twenty-six women aged between 18 and 69 years attending a university-based OCD clinic who met DSM-IV criteria for OCD according to the Structured Clinical Interview for DSM-IV Disorders were interviewed retrospectively to assess OCD onset and symptom exacerbation in relationship to reproductive events. Women were placed into 2 groups: those who had ever been pregnant (ever pregnant group) and those who had never been pregnant. The ever pregnant group was further subdivided into those who reported onset of OCD in the perinatal period (perinatal-related group) and those who denied onset related to pregnancy (nonperinatal-related group). Between-group comparisons were done using a Student t test for continuous measures, and categorical variables were assessed using the χ² test.

Results: Of the 78 women in the ever pregnant group, 32.1% (n = 24) had OCD onset in the perinatal period (perinatal-related group), 15.4% in pregnancy, 14.1% at postpartum, and 1.3% after miscarriage. Of 132 total pregnancies, 34.1% involved an exacerbation of symptoms, 22.0% involved an improvement in OCD symptoms, and 43.9% did not change symptom severity in women with preexisting illness. Women in the perinatal-related group and women with perinatal worsening of preexisting OCD were more likely to have premenstrual worsening of OCD symptoms compared to women in the nonperinatal-related group (66% vs 39%, P = .047).

Conclusions: Findings from this study provide additional evidence that pregnancy and childbirth are frequently associated with the onset of OCD or worsening of symptoms in those with preexisting disorder. In addition, there appears to be continuity between OCD onset and/or exacerbation across the reproductive life cycle, at least with menstruation and pregnancy.

retrospective reports. A study by Labad et al found that OCD onset occurred in the same year as menarche in 22% of their subjects, and that premenstrual mood symptoms (including anxiety, irritability, mood lability, and depressed mood) were associated with both premenstrual worsening of primary OCD symptoms, and onset or worsening of OCD during the puerperium. In addition, patients with an onset or exacerbation of OCD during the puerperium more frequently reported premenstrual worsening of symptoms and a previous history of major depressive disorder, including postpartum depression. Premenstrual dysphoria and high rates of postpartum depression have also been described in female OCD patients in general. Likewise, women with a history of premenstrual syndrome are at higher risk for postpartum depression and psychosis. To link all of these observations, it has been proposed that a common dysregulation of serotonergic neurotransmission, which can be accentuated by ovarian steroid fluctuations, may be involved in the pathophysiology of OCD, postpartum depression, and premenstrual syndrome.

The primary goal of this study was to examine the impact of pregnancy, childbirth, and menstruation on the onset and/or exacerbation of OCD in women attending a university-based OCD clinic. In addition, we sought to examine the relationship between reports of menstrual cycle exacerbation in OCD symptoms and onset or exacerbation of OCD during pregnancy and the postpartum. We hypothesized that women with OCD who reported perinatal onset or exacerbation of their symptoms would be more likely to experience premenstrual exacerbation of their OCD symptoms than those women with OCD who had at least 1 previous pregnancy without perinatal onset or exacerbation of their disorder. Furthermore, we hypothesized that the women with perinatal onset or exacerbation of OCD would report a more acute onset of symptoms (versus a gradual onset more typically seen in OCD), corresponding to the dramatic alteration in hormone levels associated with pregnancy and parturition.

METHOD

Subjects and Recruitment

The data for this study were drawn from the medical records and interviews of women referred to the Yale OCD Clinic on the Clinical Neuroscience Research Unit at the Connecticut Mental Health Center in New Haven, Connecticut. The patients in the clinic were referred for clinical evaluation or participation in clinical research approved by the institutional internal review board at Yale University School of Medicine. All subjects gave signed informed consent for participation in the research study being conducted at the time of enrollment.

Patients enrolled in treatment protocols in the Yale OCD Clinic are administered a number of clinical assessments including a diagnostic interview, OCD severity ratings, and depression inventories via the Structured Clinical Interview for DSM-IV Disorders (SCID), the Yale-Brown Obsessive Compulsive Scale (Y-BOCS), and the Yale Depression Inventory (YDI), respectively. This information was obtained from each participant’s clinic record. Data were obtained from women between ages 18 and 69 years who met DSM-IV criteria for OCD according to the SCID and had no lifetime history of an Axis I psychotic disorder or substance dependence disorder within the previous year. All participants were fluent in English.

Interview

According to consenting procedures, women who were already discharged from the OCD clinic (13.6%) were sent a letter notifying them that a staff member would be contacting them to conduct an interview of approximately 30 minutes duration. Those who wished not to participate could indicate so by return mail or by phone. If such a request was not received, assent for participation was assumed and subjects were contacted by phone to conduct the interview. Individuals who were actively enrolled in the OCD clinic (86.4%) were interviewed when they presented for a scheduled appointment. None of the active subjects refused to complete the interview.

The primary goal of the semistructured interview, from which data for this study were extracted, was to develop a complete database of all the patients (both male and female) who had been or were enrolled in the OCD clinic. Patients were asked information regarding demographic data, clinical features of OCD and other psychiatric and medical history. The demographic data included information on age, sex, marital status (single, married, divorced, widowed), race, level of education, and occupation. The clinical features of OCD data consisted of age at onset of obsessive-compulsive symptoms and age at onset of symptoms sufficient to meet DSM-IV criteria for the disorder. Patients were asked to characterize their obsessions and compulsions from a list of target symptoms, as well as describe the onset (acute vs gradual) and course of the disease over their lifetime (episodic vs chronic).

All female patients were asked questions regarding the relationship of their OCD symptoms to reproductive events. Their obstetrical history was based on self-report: number of pregnancies, terminations, miscarriages, and gestational age at delivery. Women were asked to describe if they experienced changes in their OCD symptoms (worsening, improvement, or no change) during the premenstruum. Women who had experienced at least 1 pregnancy were asked if the onset of OCD was related to pregnancy, pregnancy loss or termination (if any), or the postpartum period. In addition, for each pregnancy, women were asked if they experienced exacerbation, improvement, or no change in their OCD symptoms during these reproductive events. While there were subjects in perimenopause and menopause, the small number of women in this category was insufficient to be included in a separate analysis.

Other variables included in the database were history of substance use, medical history, prior psychiatric history...
(including comorbid psychiatric illness), family history, and physical or psychological trauma.

**Group Assignment**

For the purposes of this study, by virtue of self-report of their obstetrical history, women were placed into 1 of 2 groups: those who had ever been pregnant (ever pregnant group) and those who had never been pregnant (never pregnant group). Those women who were in the ever pregnant group were further subdivided according to the following parameters: those who reported onset of OCD during pregnancy or the puerperium were assigned to the perinatal-related group, while those that denied onset of OCD related to pregnancy were assigned to the nonperinatal-related group.

**Statistical Analysis**

All data were summarized using descriptive statistics (means, SDs, frequencies). Continuous measures were compared between groups using a Student t test, and categorical variables were assessed using the \( \chi^2 \) test. All analyses were considered statistically significant at \( P \leq 0.05 \) and performed using SAS, version 9.1 (SAS Institute Inc, Cary, North Carolina).

**RESULTS**

**Subjects: Ever Pregnant Versus Never Pregnant Group Comparisons**

Of the 140 women in the database, 126 had sufficient data on OCD symptoms in relation to their reproductive history to be included in the study. The data from the remaining 14 subjects were not included in any analyses. Seventy-eight women reported having had at least 1 pregnancy (ever pregnant group), while 48 women reported never having been pregnant (never pregnant group).

Descriptive information for the ever pregnant and never pregnant groups is presented in Table 1. Mean ± SD age at presentation to the Yale OCD Clinic was significantly younger in the never pregnant group (32.6 ± 13.0 years) than the ever pregnant group (40.8 ± 10.8 years) \( (t_{123} = 3.82, P < .0002) \). However, there was no significant difference in age at onset of OCD in the ever pregnant group (26.0 ± 9.0 years) compared to the never pregnant group (23.8 ± 10.6 years) \( (t_{120} = 1.22, P = .70) \). Compared to women in the never pregnant group, women in the ever pregnant group were more likely to be married \( (\chi^2 = 40.5, P < .0001) \) and less educated \( (\chi^2 = 6.4, P = .04) \). Finally, there were no significant differences regarding comorbid diagnoses or family psychiatric history (including only professionally diagnosed illness). The majority of women in both groups reported a personal (65.1%) and family (85.7%) history of depression, substance abuse, and/or other anxiety disorder. Of the women who reported having comorbid psychiatric diagnoses, the majority (in all groups) said that OCD presented first.

Perinatal-Related Onset Versus Nonperinatal-Related Onset Subgroup Comparisons

In the ever pregnant group, 24 women (30.8%) fell into the perinatal-related subgroup by virtue of having reported the onset of OCD to be related to pregnancy, fetal loss, or the postpartum period. Twelve women (15.4%) in the perinatal-related subgroup reported onset during pregnancy, 1 (1.3%) had onset after a miscarriage, and 11 (14.1%) had onset during the postpartum period. Thus, approximately half of the perinatal-related subgroup...
experienced onset during pregnancy while the other half experienced onset during the puerperium. Table 1 provides descriptive information for the perinatal-related and nonperinatal-related subgroups. Mean ± SD age at admission for the perinatal-related (39.3 ± 8.2 years) and nonperinatal-related (41.5 ± 11.8) groups was similar, as was age at onset of OCD (perinatal-related subgroup, 27.0 ± 7.1; nonperinatal-related subgroup, 25.5 ± 9.8). There were only 2 significant differences in between-subgroup comparisons. First, more women in the nonperinatal-related subgroup (22.2%) than in the perinatal-related subgroup (4.2%) carried a comorbid diagnosis in the “other” category ($\chi^2_{1} = 3.9, P = .05$). This category included diagnoses such as trichotillomania, eating disorders, and Tourette’s syndrome. Second, women in the nonperinatal-related subgroup (22.2%) were more likely to report a family history of substance abuse than women in the perinatal-related subgroup (4.2%) ($\chi^2_{1} = 3.9, P = .05$). While the Y-BOCS scores obtained on admission to the OCD clinic were available on roughly half of the women in each subgroup, there was a trend for women in the perinatal-related subgroup (29.5 ± 7.0) to have higher Y-BOCS scores than women in the nonperinatal-related subgroup (25.7 ± 4.9) ($t_{35} = 1.93, P = .06$). The Y-BOCS scores in this range are consistent with moderate to severe illness. This is reflected in the baseline Global Assessment of Functioning (GAF) scores, which were lower in the perinatal-related subgroup (51.6 ± 7.1) but not significantly different from that in the nonperinatal-related subgroup (56.3 ± 14.0).

Course and Characteristics of OCD

*Ever pregnant group and never pregnant group comparisons.* As stated, there was no significant difference found between the ever pregnant and never pregnant groups in the age at onset of OCD, and the vast majority (greater than 95%) described their course of illness as chronic rather than episodic (data not shown). As seen in Table 2, a greater proportion of women who had been pregnant reported acute onset of symptoms (47.8%), but this did not differ statistically from women who had never been pregnant (30.6%) ($\chi^2_{1} = 2.56, P = .11$).

The frequency of specific types of OCD symptoms in the ever pregnant and never pregnant groups is depicted in Table 3. Significant differences in specific types of symptoms were present only for ordering/arranging compulsions ($\chi^2_{1} = 5.51, P = .02$), religious/scrupulosity obsessions ($\chi^2_{1} = 6.01, P = .01$), and miscellaneous compulsions ($\chi^2_{1} = 6.633, P = .01$). There was also a trend for women in the never pregnant group to report having sexual obsessions ($\chi^2_{1} = 3.25, P = .07$) and a greater number of symptoms overall ($t_{23} = 1.8, P = .07$).

**Perinatal-related and nonperinatal-related subgroup comparisons.** Women with perinatal-related onset of OCD had a similar number of pregnancies as those with OCD onset unrelated to the perinatal period (Table 2). Onset of OCD with pregnancy was most likely to occur during or after the first pregnancy. A majority of women in the perinatal-related subgroup (61.9%) reported acute onset of OCD symptoms compared to 41.7% in the nonperinatal-related subgroup; however, this difference was not statistically significant ($\chi^2_{1} = 2.4, P = .12$). Of the 11 women who reported postpartum onset of OCD, 10 answered the question of how long after delivery their symptoms began. Seven of the 10 reported that the onset of their OCD occurred “right away,” while the remainder reported onset of symptoms within the first 6 months after delivery.

The type of obsessions and compulsions reported as primary symptoms by the perinatal-related and nonperinatal-related subgroups is described in Table 3. Only obsessions regarding contamination were significantly greater in the perinatal-related subgroup (66.7%) versus the nonperinatal-related subgroup (35.9%) ($\chi^2_{1} = 6.33, P = .01$). Although approximately 21% of women in both subgroups experienced obsessions regarding harming their infant in the postpartum period, there was no statistically significant difference between the groups.

**Changes in Existing OCD During Pregnancy and the Premenstruum: Group and Subgroup Comparisons**

Women in the ever pregnant group who had onset of OCD prior to becoming pregnant reported worsening of symptoms with pregnancy in 45 cases (34.1%), no change in 58 (43.9%), and improvement in 29 (22.0%). These results are
reported in terms of pregnancies (rather than percentage of women) since 9 women reported an exacerbation of OCD symptoms during 1 pregnancy, yet an improvement or no change during another. Women in the ever pregnant and never pregnant groups experienced worsening of symptoms prior to menses at approximately the same rate (49.3% of ever pregnant group, 51.6% of never pregnant group—see Table 2). When women in the perinatal-related group were combined with those women who had OCD prior to pregnancy but reported pregnancy-related worsening, there was a significant association with premenstrual worsening of OCD symptoms compared to the nonperinatal-related group, 65.5% (n = 19) vs 39.3% (n = 11), respectively ($\chi^2 = 3.93$, $P = .047$).

**DISCUSSION**

In addition to the physiologic changes during pregnancy and childbirth, there are considerable psychological and interpersonal demands on women during the transition to motherhood. The findings from our study add to the growing literature suggesting that pregnancy and childbirth can trigger the onset of OCD or the exacerbation of the ongoing disorder in a substantial number of women. Our finding that approximately 30% of women experienced a perinatal-related onset of the disorder is similar to that reported by others (15%–40%).4,11 The comorbidity rate of about 65% of mood disorders (primarily major depression) in both groups of women is also consistent with the results of previous research.25 However, in this sample and with the measures available, we did not find a significant difference between the groups in terms of family history of OCD or postpartum OCD and affective disorders.

While there was no statistically significant difference between the 2 groups of pregnant women, there was a difference in age, marital status, and education between the never pregnant and ever pregnant groups. The ever pregnant group was older, more likely to be married (70.1%), and had a greater proportion (40.8%) with a high school education or less. The majority of the never pregnant group (78.5%) had some college education. The difference in education between the groups might indicate that women pursuing higher education are more likely to postpone getting married and having children. Similarly, because they are younger, the never pregnant group is less likely to be married and have children. Therefore, difference between these groups is most likely a factor of "pregnancy" and not illness severity or symptomatology.

The predicted relationship between perinatal-related onset and/or exacerbation of OCD symptoms and worsening of OCD symptoms in the premenstruum was confirmed, suggesting that there is a “hormone-related” subtype of OCD in women. Women with perinatal-related onset of OCD or perinatal worsening of preexisting OCD are more likely to experience premenstrual exacerbation of their OCD symptoms when compared to those women whose onset of OCD did not coincide with pregnancy and whose symptoms appeared to be unaffected by pregnancy. This latter finding is similar to what has been observed between premenstrual dysphoric disorder and postpartum depression: namely, women with premenstrual negative affect are more likely to experience depression in the postnatal period.26

This observation suggests that there may be a subgroup of women with differential sensitivity to reproductive hormones, and, as such, normal reproductive events are triggers for onset or exacerbation of OCD.

---

Our results about changes in OCD symptoms during pregnancy are in agreement with previous studies that have found both improvement and worsening of symptoms at this reproductive event.\(^5,6,13\) Again this points to a potential vulnerability to gonadal steroids. The biologic basis for this differential sensitivity remains unknown, but it has been speculated to represent the effect of genetic polymorphism in genes that regulate reproductive hormone signaling or that are regulated by reproductive hormones.\(^26\)

While gonadal steroids and their interaction with serotonin have been implicated in this "hormone-related" subtype of OCD, oxytocin is another hormone that is possibly implicated in these observations. Oxytocin is critically involved in the initiation of maternal behavior in animals,\(^27\) and cerebrospinal fluid levels of oxytocin are elevated during the third trimester of pregnancy and the early puerperium. In addition, animal models have shown an increase in oxytocin messenger ribonucleic acid in the female brain during puberty.\(^28\) There is growing evidence to suggest that oxytocin may play a role in the pathogenesis of some forms of OCD.\(^29\) Obsessions regarding the safety of others and dirt and germs, as well as compulsions such as checking and cleaning might be seen as pathological correlates of normal maternal behavior. Furthermore, it has been reported in 1 study\(^30\) but not in another\(^31\) that oxytocin was elevated in the cerebrospinal fluid of patients with OCD compared with age- and sex-matched normal control subjects. Further work is needed in this area to be able to draw any definitive conclusions, but the potential role of oxytocin in the exacerbation of OCD symptoms during the reproductive years should be considered.

Although a majority of women in the perinatal-related subgroup reported acute onset of OCD symptoms, our hypothesis that this would differ significantly from that reported by women with onset unrelated to the perinatal period was not supported. Perhaps this is the case because acute onset of OCD is not uncommon, occurring in 28% of cases, and up to 64% of patients report significant life events (major medical illness, loss of a loved one, marriage, job promotion, etc) in relationship to OCD onset.\(^32\) It could be the case that the birth of a child is a trigger for OCD onset as a result of being a major life event, independent of the impact of the hormonal milieu or psychological milestones specific to becoming a parent.

Consistent with prior research, the perinatal-related group was more likely to report contamination obsessions than the nonperinatal-related group. Interestingly, however, there was no significant difference between the groups in obsessions or compulsions related to typical postpartum maternal behaviors (ie, checking, cleaning, ordering/arranging). We hypothesized that women with postpartum OCD would be more likely to have these types of symptoms as abnormal manifestations of normal maternal behaviors related to infant care. In addition, there was no significant difference found between the perinatal-related and nonperinatal-related groups in terms of having aggressive obsessions. Perhaps this is secondary to our finding of fewer than expected women (25%) in the perinatal-related group with aggressive obsessions toward their offspring. Women may have been resistant to admitting these symptoms as a result of the stigma surrounding having these thoughts. Furthermore, aggression and contamination obsessions and checking and cleaning compulsions are the most common OCD symptoms, reported by 50%–75% of patients with OCD.\(^33\)

Based on the retrospective studies, as many as 11%–47% of women have their first onset of OCD in the peripartum period.\(^5,6,14\) Our results also suggest that both pregnancy and the postpartum may be periods of risk for the initiation of OCD, with the 2 periods conferring relatively equal risk. However, OCD in the peripartum period is likely an underdiagnosed entity. Thus, it is crucial for health care providers to inquire about these problems and be aware of their potential consequences so that early intervention may take place. For example, women should be reassured that the occurrence of intrusive ego-dystonic thoughts is common so that they may receive appropriate care without having to suffer in silence. In addition, even if no physical harm is done to the infant as a result of a mother's obsessional thoughts, these thoughts may negatively affect the infant's development in a variety of ways. Mothers who fear harming their infants may avoid them as a result, preventing the development of a secure mother-child relationship and affecting proper infant care. Moreover, these obsessional thoughts likely affect a mother's confidence in her abilities and may further hinder the development of a close relationship with her child.\(^35\) Increasing data show that a poor early interaction between the parent and the infant may have long-term detrimental effects on the child, including increased vulnerability to stress and an increased risk for developing psychiatric disorders later in life.\(^36,37\) Animal studies have also highlighted the importance of early mothering in determining the future maternal behavior of the adult offspring.\(^38,39\)

That approximately half (46%–56%) of all of the women in this study, regardless of pregnancy history, reported a worsening of OCD symptoms during the premenstruum suggests that clinicians should consider the premenstruum as a trigger for symptom exacerbation and make decisions regarding treatment accordingly. Women with OCD who feel that their symptoms worsen in the premenstruum should keep a daily diary of symptom severity similar to that which is done by women undergoing evaluation for premenstrual dysphoric disorder. As a goal for future research, it would be interesting to prospectively assess the premenstruum and the puerperium in the same group of patients to determine if worsening of OCD during the premenstruum could act as a predictor of worsening or onset related to pregnancy.

The results of this study, and prior research, are limited by their reliance on retrospective recall. Patients often cannot accurately determine precise details of symptom history or events related to onset potentially leading to recall bias.
Women who participated in this study varied in the number of years since onset of OCD. Thus, recall of events proximal to the onset of OCD may have become linked to disorder onset. For some women this may have limited their ability to distinguish between pregnancy and the postpartum period when asked to recall changes in their symptoms at that time. In addition, the psychological impact of becoming pregnant and caring for an infant may have brought to the forefront OCD symptoms that may have been present but otherwise undetected or easily managed. This could have led to misclassification of preexisting OCD as new onset in the perinatal context. Given these limitations, definitive conclusions about the relationship between reproductive events and onset or worsening of OCD should be taken with caution. Prospective assessments or assessment more proximal to the time of delivery could address this weakness in the present research. Moreover, future prospective studies are necessary to further clarify the prevalence of OCD during pregnancy and the postpartum period, as well as to identify subgroups of women who may be particularly vulnerable to the development of this disorder.

The generalization of our results is also limited by the patient population studied. Our sample was formed by women attending an OCD research clinic, which may lead to an overrepresentation of women with more severe symptoms and comorbidities. In addition, the majority of our sample consisted of white women. Both of these factors limit the generalization of our results to the population at large. However, this is not unlike other studies that have examined OCD in relationship to reproductive events. In contrast to prior studies, our study has a never pregnant comparison group, which enhances the importance of our results.

Despite the limitations acknowledged above, our findings provide additional evidence that pregnancy and childbirth are frequently associated with the onset of OCD or worsening of symptoms in those with preexisting disorder. In addition, the results of our research point to the relatively significant role of gonadal hormones in this phenomenon; there appears to be continuity between OCD onset and/or exacerbation across the reproductive life cycle, at least with respect to menstruation and pregnancy. Appreciating and understanding the role these hormones play in influencing the course of OCD may help to elucidate potential neurobiological mechanisms of this psychopathology, and will hopefully lead to the development of new concepts in treatment. However, concurrent with these hormonal fluctuations are dramatic and potentially stressful changes in the mother’s psychosocial and interpersonal situation. Future studies will need to be designed in such a manner to begin to tease apart the relative contributions incorporated in the biopsychosocial model of the pathogenesis of OCD in the perinatal context.
